This Letter reports on the first results from the Taiwan Axion Search Experiment with Haloscope, a search for axions using a microwave cavity at frequencies between 4.70750 and 4.79815 GHz. Apart from the non-axion signals, no candidates with a significance more than 3.355 were found. The experiment excludes models with the axion-two-photon coupling $|g_{a\gamma\gamma}| \gtrsim 8.2 \times 10^{-14} \text{ GeV}^{-1}$, a factor of eleven above the benchmark KSVZ model in the mass range $19.4687 < m_a < 19.8436 \mu\text{eV}$, reaching a sensitivity three orders of magnitude better than any existing limits. It is also the first time that a haloscope-type experiment places constraints on the $g_{a\gamma\gamma}$ in this mass region.

Various astrophysical and cosmological observations indicate that dark matter (DM) exists and makes up 26.4% of the total energy density of the universe [1–5]. One of the viable dark matter candidates is the axion, which arises from the spontaneous breaking of a new global $U(1)_{\text{PQ}}$ symmetry [6] introduced by Peccei and Quinn to solve the strong CP problem [6–8]. Axions are abundantly produced during the QCD phase transition in the early universe and may constitute the DM. In the post-inflationary PQ symmetry breaking scenario, current calculations suggest a mass range of $\mathcal{O}(1\text{--}100) \mu\text{eV}$ for axions so that the cosmic axion density does not exceed the observed cold DM density [9–21].

Axions could be detected and studied via their two-photon interaction, the so-called “inverse Primakoff effect”, of which the strength is described by the coupling constant $g_{a\gamma\gamma}$. The detectors with the best sensitivities to axions with a mass of $m_a \approx \mu\text{eV}$, as first proposed by Sikivie [22, 23], are haloscopes consisting of a microwave cavity immersed in a strong static magnetic field and operated at a cryogenic temperature. In the presence of an external magnetic field, the ambient oscillating axion field drives the cavity and they resonate when the frequencies of the electromagnetic modes in the cavity match the microwave frequency f , where f is set by the total energy of the axion: $hf = E_a = m_a c^2 + \frac{1}{2} m_a v^2$. The axion signal power is further delivered to the read-out probe followed by a low-noise linear amplifier.

Several haloscope experiments have actively carried out axion searches, and a few have reached or approached the benchmark values of $g_{a\gamma\gamma}$. The most significant efforts are from the Axion Dark Matter eXperiment (ADMX), placing tight constraints within the mass range of 1.9–4.2 μeV [24–30]. Others include the

Haloscope at Yale Sensitive to Axion Cold dark matter (HAYSTAC) [31–33], the Center for Axion and Precision Physics Research (CAPP) [34–36], and the QQuest for AXions- $a\gamma$ (QUAX- $a\gamma$) [37]. This Letter presents the first results of a search for axions in the mass range of 19.4687–19.8436 μeV , from the Taiwan Axion Search Experiment with Haloscope (TASEH).

The detector of TASEH is located at the Department of Physics, National Central University, Taiwan and housed within a cryogen-free dilution refrigerator (DR) from BlueFors (greater details in Ref. [38]). A superconducting solenoid with a bore diameter of 76 mm and a length of 240 mm is integrated with the DR. During the data taking, the cavity sat in the center of the magnet bore and was connected via holders to the mixing flange of the DR at a temperature of $T_{\text{mx}} \simeq 27 \text{ mK}$. The temperature of the cavity stayed at $T_c \simeq 155 \text{ mK}$, higher with respect to the DR; it is believed that the cavity had an unexpected thermal contact with the radiation shield in the DR. The cavity, made of oxygen-free high-conductivity (OFHC) copper, has an effective volume of $V = 0.234 \text{ L}$ and is a two-cell cylinder split along the axial direction. The cylindrical cavity has an inner radius of 2.5 cm and a height of 12 cm. In order to maintain a smooth surface, the cavity underwent the processes of annealing, polishing, and chemical cleaning. The resonant frequency can be tuned via the rotation of an off-axis OFHC copper tuning rod, from the position closer to the cavity wall to the position closer to the cavity center. An output probe, made of a 50- Ω semi-rigid coaxial cable that was soldered to an SMA (SubMiniature version A) connector, was inserted into the cavity. The signal from the output probe was directed to an impedance-matched amplification chain. The first-stage amplifier was a low

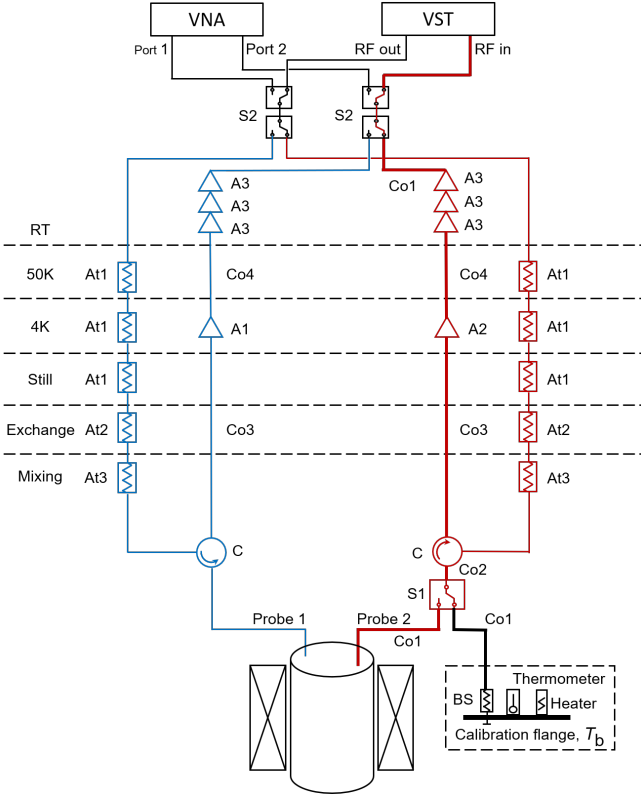

FIG. 1. The schematic diagram of the TASEH microwave system.

noise high-electron-mobility transistor (HEMT) amplifier mounted on the 4K flange. The signal was further amplified at room temperature via a three-stage post-amplifier, and down-converted and demodulated to in-phase (I) and quadrature (Q) components and digitized by an analog-to-digital converter with a sampling rate of 2 MHz. Figure 1 shows the schematic of the TASEH microwave system, which was used to examine the cavity characteristics, to perform the calibration of the amplification chain, and to carry out the axion detection experiment.

The signal power extracted from a microwave cavity on resonance is given by:

$$P_s = \left(g_\gamma^2 \frac{\alpha^2 \hbar^3 c^3 \rho_a}{\pi^2 \Lambda^4} \right) \times \left(\omega_c \frac{1}{\mu_0} B_0^2 V C Q_L \frac{\beta}{1 + \beta} \right). \quad (1)$$

The first set of parentheses contains physical constants, a dimensionless model-dependent parameter g_γ , and the local dark-matter density $\rho_a = 0.45 \text{ GeV/cm}^3$ [5, 39]. The numerical values of g_γ are -0.97 and 0.36 in the Kim-Shifman-Vainshtein-Zakharov (KSVZ) [40, 41] and the Dine-Fischler-Srednicki-Zhitnitsky (DFSZ) [42, 43] benchmark models, respectively. For the QCD axions, the $g_{a\gamma\gamma}$ is related to g_γ and the axion mass m_a :

$$g_{a\gamma\gamma} = \left(\frac{g_\gamma \alpha}{\pi \Lambda^2} \right) m_a, \quad (2)$$

where α is the fine-structure constant and $\Lambda = 78 \text{ MeV}$

is a scale parameter that can be derived from the mass and the decay constant of the pion and the ratio of the up to down quark masses. The second set of parentheses contains parameters related to the experimental setup: the angular resonant frequency of the cavity ω_c , the vacuum permeability μ_0 , the nominal strength of the external magnetic field B_0 , the volume of the cavity V , and the loaded quality factor of the cavity $Q_L = Q_0/(1 + \beta)$, where Q_0 is the unloaded, intrinsic quality factor of the cavity and β is the coupling coefficient which determines the amount of coupling of the signal to the receiver. The form factor C is the normalized overlap of the electric field \vec{E} , for a particular cavity resonant mode, with the external magnetic field \vec{B} :

$$C = \frac{\left[\int (\vec{B} \cdot \vec{E}) d^3x \right]^2}{B_0^2 V \int E^2 d^3x}. \quad (3)$$

Here, the magnetic field \vec{B} points mostly along the axial direction of the cavity. The field strength has a small variation along the radial and axial directions and $B_0 = 8 \text{ Tesla}$ is the nominal magnetic field strength. For cylindrical cavities, the largest form factor is from the TM_{010} mode. The expected signal power derived from the experimental parameters of TASEH is $P_s \simeq 1.5 \times 10^{-24} \text{ W}$ for a KSVZ axion with a mass of $19.5 \mu\text{eV}$.

In the axion experiments, the figure of merit that determines the design of the experimental setup is the signal-to-noise ratio (SNR), i.e. the ratio of the signal power P_s to the fluctuation in the averaged noise power spectrum σ_n . According to Dicke's Radiometer Equation [44], the σ_n is given by:

$$\sigma_n = k_B T_{\text{sys}} \sqrt{\frac{\Delta f}{t}} \quad (4)$$

where T_{sys} is the system noise temperature, an effective temperature associated with the total noise of the system, t is the data integration time t and Δf is the resolution bandwidth. Assuming that all the axion signal power falls within Δf , the SNR will therefore be:

$$\text{SNR} = \frac{P_s}{\sigma_n} = \frac{P_s}{k_B T_{\text{sys}}} \sqrt{\frac{t}{\Delta f}}. \quad (5)$$

The system noise temperature T_{sys} has three major components:

$$T_{\text{sys}} = \tilde{T}_{\text{mx}} + \left(\tilde{T}_c - \tilde{T}_{\text{mx}} \right) L(\omega) + T_a, \quad (6)$$

where ω is the angular frequency. The last term T_a is the effective temperature of the noise added by the receiver (mainly from the first-stage amplifier). The sum of the first two terms is equivalent to the sum of the reflection of the incoming noise from the attenuator anchored to the mixing flange and the transmission of the noise from the

cavity body itself. The $\tilde{T}_i = \left(\frac{1}{e^{\hbar\omega/k_B T_i} - 1} + \frac{1}{2} \right) \hbar\omega/k_B$ refers to the effective temperature due to the blackbody radiation at a physical temperature T_i and the vacuum fluctuation. The $T_c \simeq 155$ mK and $T_{\text{mx}} \simeq 27$ mK are the physical temperatures of the cavity and of the mixing flange, respectively. The difference of the effective temperatures $\tilde{T}_c - \tilde{T}_{\text{mx}}$ is modulated by a Lorentzian function $L(\omega)$. The derivation of the first two terms in Eq. (6) can be found in Ref. [45]. Using the operation parameters of TASEH and the results from the calibration of readout electronics, the value of T_{sys} for TASEH is about 2.0–2.3 K.

The data for the analysis presented here were collected by TASEH from October 13, 2021 to November 15, 2021, and are termed as the CD102 data, where CD stands for “cool down”. The CD102 data cover the frequency range of 4.70750–4.79815 GHz. In this Letter, all the frequencies in unit of GHz are quoted with five decimal places as the absolute accuracy of frequency is ≈ 10 kHz. It shall be noted that the frequency resolution is 1 kHz. The form factor C for the TM₀₁₀ mode varies from 0.60 to 0.61 over the operational frequency range. The intrinsic, unloaded quality factor Q_0 at the cryogenic temperature ($T_c \simeq 155$ mK) is $\simeq 60700$. There were 837 resonant-frequency steps in total, with a frequency difference of $\Delta f_s = 95 - 115$ kHz between the steps. The value of Δf_s was kept within 10% of 105 kHz rather than a fixed value, such that the rotation angle of the tuning rod did not need to be fine-tuned and the operation time could be minimized; a 10% variation of the Δf_s is found to have no impact on the $|g_{a\gamma\gamma}|$ limits. Each resonant-frequency step is denoted as a “scan” and the data integration time was about 32–42 minutes. The integration time was determined based on the target $|g_{a\gamma\gamma}|$ limits and the experimental parameters; the variation of the integration time aimed to remove the frequency-dependence in the $|g_{a\gamma\gamma}|$ limits caused by frequency dependence of the added noise T_a . The depth of the output probe was set for $\beta \simeq 2$ since this value maximizes the scan rate, namely the coverage of frequency scans for a given amount of time.

In order to perform a calibration for the amplification chain, the HEMT was connected to a heat source (a 50- Ω resistor) instead of the cavity; various values of input currents were sent to the source to change its temperature monitored by a thermometer. The power from the source was delivered following the same transmission line as that in the axion data running. The output power is fitted to a first-order polynomial, as a function of the source temperature, to extract the gain and added noise T_a for the amplification chain. The value of T_a is about 1.9 – 2.2 K.

The analysis of the TASEH CD102 data follows the procedure similar to that developed by the HAYSTAC experiment [46] and the details are described in Ref. [45]. The fast Fourier transform (FFT) algorithm is performed

on the IQ time series data to obtain the frequency-domain power spectrum. The Savitzky-Golay (SG) filter [47] is applied to remove the structure of the background in the frequency-domain power spectrum. All the spectra from different frequency scans are combined with a weighting algorithm. In order to maximize the SNR, a running window of five consecutive bins in the combined spectrum is applied and the five bins within each window are merged to construct a final spectrum. The five frequency bins correspond to the 5-kHz axion signal line width, derived from the standard assumption of axion signal line shape as described by Eq. (7). This signal line shape is also used when defining the maximum likelihood weights for merging:

$$\mathcal{F}(f, f_a) = \frac{2}{\sqrt{\pi}} \sqrt{f - f_a} \left(\frac{3}{\alpha} \right)^{3/2} e^{-\frac{3(f - f_a)}{\alpha}}, \quad (7)$$

where $\alpha \equiv f_a \langle v^2 \rangle / c^2$. Here, the frequency f must be greater or equal to the axion frequency $f_a = m_a c^2 / h$. In this standard assumption of axion signal line shape, the DM halo density distribution is assumed to be spherically symmetric and close to be isothermal, which results in a velocity distribution similar to the Maxwell-Boltzmann distribution. Therefore, the variance $\langle v^2 \rangle$ and the most probable velocity (speed) v_p are related to each other: $\langle v^2 \rangle = 3v_p^2/2 = (270 \text{ km/s})^2$, where $v_p = 220 \text{ km/s}$ is the local circular velocity of DM in the galactic rest frame.

After the merging, if there were any potential signal with an SNR larger than 3.355, a rescan would be proceeded to check if it were a real signal or a statistical fluctuation. The procedure of the CD102 data taking was to perform a rescan after covering every 10 MHz; the rescan was done by adjusting the tuning rod of the cavity so to match the resonant frequency to the frequency of the candidate. In total, 22 candidates with an SNR greater than 3.355 were found. Among them, 10 candidates were from the fluctuations because they were gone after a few rescans. The remaining two candidates, in the frequency ranges of 4.71017 – 4.71019 GHz and 4.74730 – 4.74738 GHz, are excluded from consideration of axion signal candidates. The signal in the second frequency range was detected via a portable antenna outside the DR and found to come from the instrument control computer in the laboratory, while the signal in the first frequency range was not detected outside the DR but still present after turning off the external magnetic field. Therefore, no limits are placed for the above two frequency ranges.

Since no candidates were found after the rescan, the upper limits at 95% confidence level (C.L.) on the $|g_\gamma|$ and the $|g_{a\gamma\gamma}|$ are derived by setting the maximum SNR equal to five. Figure 2 shows the limits on the $|g_{a\gamma\gamma}|$ from TASEH and the ratio of the limits on the $|g_\gamma|$ with respect to the KSVZ benchmark value ($|g_{\text{KSVZ}}| = 0.97$) from TASEH together with those from the previous searches. The limits on $|g_{a\gamma\gamma}|$ range from $5.3 \times 10^{-14} \text{ GeV}^{-1}$ to $8.9 \times$

$10^{-14} \text{ GeV}^{-1}$, with an average value of $8.2 \times 10^{-14} \text{ GeV}^{-1}$; the lowest value comes from the frequency bins with additional eight times more data from the rescans, while the highest value comes from the frequency bins near the boundaries of the spectrum. The analysis that merges bins without assuming a signal line shape results in $\approx 5.5\%$ larger values on the $|g_{a\gamma\gamma}|$ limits. If a Gaussian signal line shape with an FWHM of 2.5 kHz, about half of the axion line width in Eq. (7), is assumed instead, the limits will be $\approx 3.8\%$ smaller than the central results. If the $|g_{a\gamma\gamma}|$ limits are derived from the observed SNR as described in the ADMX paper [48], rather than using the 5σ target SNR, the average limit on $|g_{a\gamma\gamma}|$ will be $\approx 4.9 \times 10^{-14} \text{ GeV}^{-1}$. Overall the total relative systematic uncertainty is $\approx 4.6\%$, coming from the uncertainties on the loaded quality factor Q_L , the coupling coefficient β , the added noise temperature T_a , the effect of the misalignment between the true axion frequency and the lower boundaries of the frequency bins, and the variation of the SG-filter parameters.

After the collection of the CD102 data, the synthetic axion signals were injected into the cavity and read out via the same transmission line and amplification chain. The procedure to generate axion-like signals is summarized in Ref. [38] and the analysis of the synthetic axion data is described in Ref. [45]. The analysis results of the synthetic axion signals demonstrates the capability of the experimental setup and the analysis strategy to discover an axion signal with $|g_\gamma| \approx \mathcal{O}(10 |g_{\text{KSVZ}}|)$.

This Letter presents the first results of a search for axions for the mass range $19.4687 < m_a < 19.8436 \mu\text{eV}$. Apart from the non-axion signals, no candidates with a significance more than 3.355 were found. The experiment excludes models with the axion-two-photon coupling $|g_{a\gamma\gamma}| \gtrsim 8.2 \times 10^{-14} \text{ GeV}^{-1}$ at 95% C.L., a factor of eleven above the benchmark KSVZ model. The sensitivity on $|g_{a\gamma\gamma}|$ reached by TASEH is three orders of magnitude better than the existing limits. It is also the first time that a haloscope-type experiment places constraints in this mass region.

We thank Chao-Lin Kuo for his help to initiate this project as well as discussions on the microwave cavity design, Gray Rybka and Nicole Crisosto for their introduction of the ADMX experimental setup and analysis, Anson Hook for the discussions and the review of the axion theory, and Jiunn-Wei Chen, Cheng-Wei Chiang, Cheng-Pang Liu, and Asuka Ito for the discussions of future improvements in axion searches. The work of the TASEH Collaboration was funded by the Ministry of Science and Technology (MoST) of Taiwan with grant numbers MoST-109-2123-M-001-002, MoST-110-2123-M-001-006, MoST-110-2112-M-213-018, MoST-110-2628-M-008-003-MY3, and MoST-109-2112-M-008-013-MY3, and by the Institute of Physics, Academia Sinica.
